A 77-year-old woman with hypertension, hypercholesterolemia, and an episode of pulmonary embolism 4 weeks before hospitalization, on oral anticoagulation, was referred to our institution with a suspicion of an intracardiac tumor in the left ventricle. The patient presented with mild exertional dyspnea and a low-degree systolic murmur. Two-dimensional transthoracic echocardiography (TTE) revealed an irregular mass (long-axis view, 26 × 17 mm; 4-chamber view, 28 × 20 mm) attached to the mitral valve (MV) annulus, partially involving the MV posterior leaflet. On TTE, the pathological mass showed a calcified rim and central echolucencies (Figure 1A). The echocardiographic features of the mass were not typical for a thrombus or myxoma. Despite the turbulence of mitral inflow caused by the mass, no evidence of mitral stenosis was present (mean gradient, 2 mm Hg; MV area >2.5 cm²). Additionally, 2 jets of mild mitral regurgitation were detected (Figure 1B). To assess the mass more precisely, its characteristics and their relation to the surrounding structures, 3-dimensional transesophageal echocardiography was performed, revealing a round, highly echogenic mass in the middle region of the mitral posterior leaflet (P2 scallop), with a smooth surface (Figure 1C and 1D) and without detectable intratumor blood flow on color Doppler ultrasound.

Cardiac magnetic resonance (CMR) showed a low-signal intensity mass (4-chamber view, 26 mm in length) on T₁- and T₂-weighted images (Figure 1E–1H), and a caseous calcification of the mitral annulus (CCMA) was suggested. Subsequent cardiac computed tomography revealed major calcifications of the lesion, which confirmed the CMR diagnosis of CCMA (Figure 1I and 1J). Because the patient had no significant MV dysfunction, she was excluded from surgery. Importantly, follow-up TTE performed at 6 and 12 months showed no progression of the “tumor”.

Mitral annular calcification is a well-known degenerative process and a common finding on TTE, whereas CCMA is a very rare variant of mitral annular calcification. Although mitral annular calcification is associated with older age and chronic kidney disease, the pathophysiology of CCMA has not been established. Interestingly, CCMA may mimic intracardiac tumor or abscess. However, its location in the posterior part of the mitral annulus and typical central echolucency surrounded by a hyperechogenic rim, without any flow and no acoustic shadow, can help in the echocardiographic differential diagnosis. The CMR and CT images are highly characteristic and support the final diagnosis without the need for further histological examination.

CCMA is benign and often asymptomatic. However, it may cause significant mitral inflow obstruction or embolic stroke and may be an indication for surgical removal. In patients who underwent surgery, microscopic examinations of caseous material evacuated from a calcified envelope revealed amorphous eosinophilic acellular material, surrounded by macrophages and lymphocytes, with no neoplastic cells. In our patient, the diagnosis of CCMA was based only on typical findings of multimodal noninvasive imaging. It seems that echocardiographic follow-up of this rare phenomenon is sufficient in asymptomatic patients. However, surgery should always be considered in cases of uncertain diagnosis, peripheral embolism, or valve dysfunction.
